A Brief Introduction to TensorFlow

Dylan Slack

Agenda

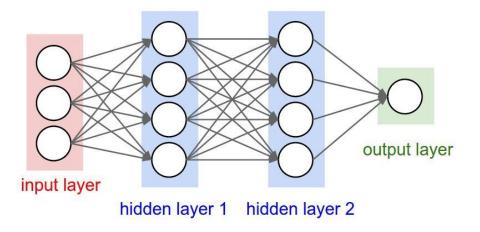

- Introduce the TensorFlow computing paradigm
- Give some live coding examples along the way
- This code is all available on my github:
 - https://github.com/dylan-slack/tf_tutorial

Why TensorFlow (TF)?

- It gives us the tools to build, train, and evaluate machine/deep learning models
- It's one of the most popular, widely used tools to do this
- Other tools include, pytorch, caffe, torch, mxnet, etc.

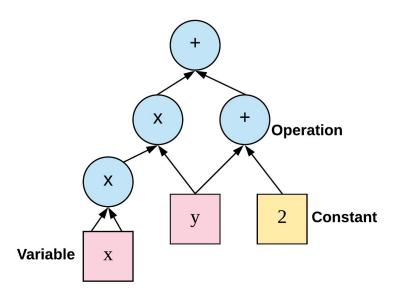

What do we mean by "Deep Learning?"

 Models such as neural networks that use many parameters to approximate complex, non-linear functions

Introducing the TF Computing Paradigm

 TensorFlow requires that you first set up a graph that defines your computation

TF Computing

- Once you've defined a graph, you can call a session to execute operations on the graph
- We evaluate tensors on the graph
 - Tensors are n-dimension arrays
- Sessions control the environment where you evaluate tensors

Let's look at some code

Check out slide 7 in the github repo

TensorFlow Data Types

- Constants: tf.constant(..)
 - Constants are hardcoded into the defintion of the graph
 - They making loading a graph with many constants a costly operation

TensorFlow Data Types

- Variables: tf.Variable(...)
 - Variables are... variables, they maintain the state of the graph across calls to run
 - Unlike constants they must be initialized

More On Sessions

- Each session has its own copy of variables
- Variables can hold different values across different sessions and that's ok!

TensorFlow Data Types

- Placeholders: tf.placeholder(...)
 - Assemble the graph without the values needed for computation
 - Include the values through a feed_dict at run time

Optimizers

- Optimizers are really where the "magic" starts to happen in TF
- They allow us to compute and apply gradients to our graphs in order to optimize variables
- TF has many different types of optimizers -here is a good post on why there are so many:

https://stackoverflow.com/questions/36162180/gradient-descent-vs-adagrad-v

Linear Regression Model

Model:

$$y_{pred} = X \cdot \theta + b$$

Loss (Optimization Goal):

$$\mathcal{L}_{\theta} = \frac{1}{2n} \sum_{i=1}^{n} (y_i - y_{pred_i})^2$$

Linear Regression Optimization

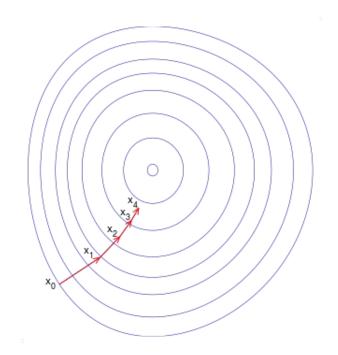

- Intuition: We want to make updates to θ such that we minimize the loss
- How? We perform gradient descent

$$\theta_{i+1} = \theta_i - \alpha \nabla_{\theta} \mathcal{L}_{\theta}$$

= $\theta_i - \alpha (y^{(i)} - y^{(i)}_{pred}) x^{(i)}$

Gradient Descent Illustration

- If this is our loss function, our configurations of theta will place us somewhere initially
- We take small steps to minimize our loss by adjusting theta

Connecting this back to TF

 If we define a differentiable loss function, TF can automatically take the gradient and perform the optimization in one call

optimizer = tf.train.GradientDescentOptimizer(learning_rate=LEARNING_RATE).\
minimize(loss) #<< 50 easy!!!!</pre>

Linear Regression Example

- See Part 2 in the notebook
- We predict housing prices using the boston housing dataset

Next Steps

- You can use these same techniques to build and optimize neural networks
- TF is a highly extensive and actively changing piece of software
